ABSTRACT

Objective: To assess and compare the diagnostic ability of ultrasound (US) and 99 mTc-MIBI planar scintigraphy in a combination with single-photon-emission computed tomography/computed tomography (SPECT/CT) for the pre-operative evaluation of primary hyperparathyroidism.

Methods: We retrospectively reviewed 60 patients who underwent parathyroidectomy for primary hyperparathyroidism. All patients had to undergo pre-operative Tc-99m MIBI planar scintigraphy+SPECT/CT and US examinations to be included in the study. All US examinations were performed by the single experienced operator. The diagnostic accuracy of the imaging methods was assessed by using the surgical pathology as a reference method.

Results: Surgical pathology revealed solitary parathyroid adenoma in 54 patients and multiglandular disease in five patients (hyperplasia in four patients and adenoma in one patient). The sensitivity and the diagnostic accuracy of US in detecting solitary adenoma were 88.9% and 87.2%, respectively, while the sensitivity and the diagnostic accuracy of Tc-99m MIBI planar scintigraphy+SPECT/CT were 96.3% and 94.5%, respectively. However, the combination of the two methods was able to detect all solitary adenomas. The overall diagnostic accuracy of US, Tc-99m MIBI planar scintigraphy+SPECT/CT, and the combination of the modalities for solitary lesions and multiglandular disease were 86.6%, 90%, and 96.6%, respectively.

Conclusion: The US and Tc-99m MIBI planar scintigraphy+SPECT/CT had an excellent diagnostic ability in assessing patients with primary hyperparathyroidism in the pre-operative period; however, the combination of these methods showed even a more superior diagnostic accuracy and sensitivity, reaching up to 96.6% and 98.3, respectively. We highlight that the combination of these two methods should always be preferred in the pre-operative assessment of parathyroid adenoma.

Keywords: Hyperparathyroidism, parathyroid adenoma, parathyroid hyperplasia, ultrasound, Tc-99m MIBI-sestamibi, scintigraphy, SPECT/CT

INTRODUCTION

Hyperparathyroidism is defined as an increased level of parathyroid hormone and can be classified as primary, secondary, and tertiary hyperparathyroidism. Over functioning of the gland itself due to adenoma or hyperplasia is classified as primary hyperparathyroidism (PHPT), and approximately 80% of PHPT cases occurs due to parathyroid adenomas (1). Although PHPT typically involves the musculoskeletal system, particularly bones, the disease can manifest with diverse clinical symptoms and findings, including peptic ulceration, alterations in the mental status, and nephrolithiasis (1, 2). Traditionally, conventional bilateral neck exploration was the method of choice for the operation, but there has been a recent trend toward minimally invasive parathyroidectomy (MIP), mostly

given the technological advancements of the pre-operative imaging methods (3-6). The success of MIP has been endorsed by many studies, showing that while MIP has comparable curative rates with the traditional approaches, it also offers lower complication rates, reduced costs, substantially shorter operation and post-operative hospitalization time, and better cosmetic results (4-6).

Conventional ultrasound (US) and 99 mTc-MIBI scintigraphy are the most widely used modalities in the pre-operative evaluation of the patients with suspicion of PHPT secondary to parathyroid disease. To date, many studies have investigated and favored the diagnostic value of these two methods in detecting parathyroid adenomas, although a considerably wide range of sensitivity has been reported (7-11).

Herein, we aimed to assess and compare the diagnostic value of pre-operative US and 99 mTc-MIBI planar scintigraphy in combination with single-photon-emission computed tomography/computed tomography (SPECT/CT) for the pre-operative evaluation of PHPT.

METHODS

A local ethics committee approved this retrospective study, which was carried out from January 2006 to January 2018. A need of informed consent was waived by the ethic board for the retrospective review of the clinical and radiologic data of patients. A total of 60 patients with clinically and biochemically proven PHPT (increased intact PTH, increased serum calcium, and normal kidney functions) were included in the study. All patients had to have a pre-operative US and 99 mTc-MIBI+SPECT/CT scan to be eligible for the study. Patients with recurrent or persistent hyperparathyroidism, a history of former thyroid or parathyroid operation, and a history of any neck malignancy were excluded from the study.

99 mTc-MIBI+SPECT/CT and US examinations

Dual-phase parathyroid scintigraphy using the 99 mTc-MIBI was utilized for all patients. First, 740 MBq of 99 mTc-MIBI were given to patients, and then immediate (at 10 minutes) and delayed (at 180 minutes) images were obtained. The immediate phase comprised static images of the chest on the anterior plane at 10 minutes, and static images of the neck on the anterior, left and right, and left oblique planes at 5 minutes after the injection. All acquisitions were handled using a low-energy, high-resolution parallel-hole collimator with a matrix size 256x256 and a 1.85x zoom level. Afterward, static anterior left and right oblique plane images were obtained from a distance of 10 cm from the patient's skin using a five pinhole collimator mm in diameter (matrix size, 256x256; 2.19x zoom). A dual-head gamma camera (Siemens) that was adjusted to 140keV and had a 10% width (range, 133–147 keV) was used for all planar imaging. Approximately 1 hour after the 99 mTc-MIBI administration, the neck and the upper thorax of the patients were examined with a SPECT/CT (SIEMENS INTEVO 6 xSPECT) equipped with a dual-head gamma camera (matrix size, 128x128),

which was combined with the CT system positioned on the same gantry. The CT system parameters were 2.5 mA and 130 kVp, 2x2.5 mm collimation, and 10 mm sections reconstructed in a 256x256 matrix. The delayed images consisted of the same acquisitions as for the immediate phase 5 min pinhole and parallel hole images.

Two discriminative features of parathyroid adenomas were used when interpreting scintigraphy examinations: 1) Both thyroid parenchyma and parathyroid adenomas show the 99 mTc-MIBI uptake during the early phases; however, normal thyroid gland showed faster wash-out compared to the adenomas, while adenomas showed fixed 99 mTc-MIBI uptake during the later phases; and 2) occasionally, parathyroid adenomas might also show more prominent tracer uptake during the early phases (12). Figure 1 shows a 99 mTc-MIBI planar scintigraphy+SPECT/CT image of a patient with adenoma.

The same observer with over 20 years of thyroid and parathyroid ultrasound experience performed all US examinations. The patients were directed to lay in a comfortable supine position, hyperextending their necks for the US evaluation. The operator performed all examinations with the same device (LOGIQ E9 with XDclear, General Electric (GE) Healthcare, Wauwatosa, WI, USA) using a linear array transducer (ML6-15) with a frequency range 12-15 MHz. The observer examined the neck putting a particular focus on posterior neighborhoods of the upper and the lower parts of the thyroid lobes. Given the more diverse presentation of the lower quadrant adenomas, the observer delicately explored the paratracheal regions, the area around the carotid artery, and deep regions of the neck and superior mediastinum using the oblique craniocaudal view. The observer identified parathyroid adenomas by their oval-shaped, solid, and hypoechogenic appearance compared to thyroid parenchyma. In equivocal cases, a Doppler US was also applied to identify the feeder artery, which commonly stems from the inferior thyroid artery and giving it an arc- or rim-like vascular appearance (10). The observer noted whether the adenoma was present, and if present, the exact location of the lesion, as located in the right-upper, right-lower, left-upper, and left-lower pole of the parathyroid gland. Moreover, if more than one lesion was detected, the observer also noted that lesion. The incidental or previously known pathologies of

Please note that the images are ordered from left to right and up to bottom as representing early through the late phases of the examination

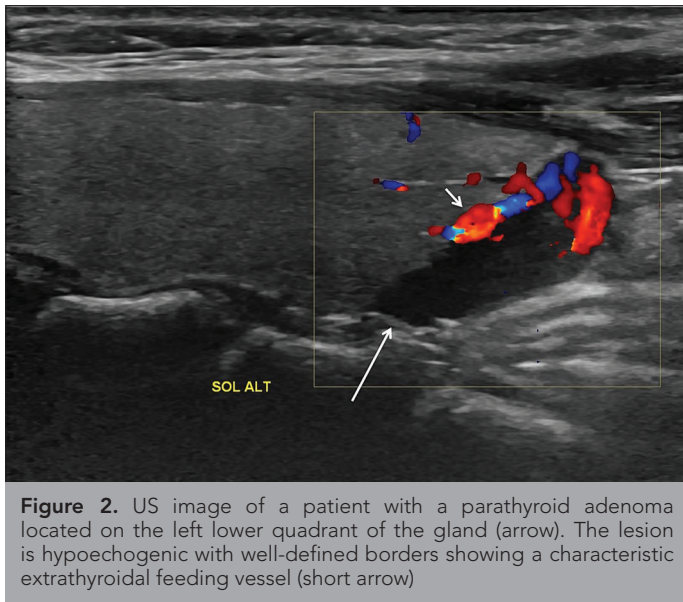

Figure 2. US image of a patient with a parathyroid adenoma located on the left lower quadrant of the gland (arrow). The lesion is hypoechoic with well-defined borders showing a characteristic extrathyroidal feeding vessel (short arrow)

the thyroid gland that were identified during the examination were also indicated for a further diagnostic workup.

Surgery

All the procedures were performed under general anesthesia. Patients with solitary parathyroid adenoma and without additional thyroid pathology were operated by one of the three surgeons in our institute using minimal invasive parathyroidectomy in light of the pre-operative US and 99 mTc-MIBI planar scintigraphy+SPECT/CT. The surgeons applied total or unilateral thyroidectomy operation with a more extensive surgical approach in appropriate cases. The adenoma location according to US and scintigraphy findings was presented as four quadrants: the right-upper, right-lower, left-upper, and left-lower quadrant. The surgeons started the operation by placing an approximately 2-3 cm transverse incision line over the proper localization of the adenoma. To prevent damage, the recurrent laryngeal nerve was carefully monitored during the procedure. If a thyroid operation was necessary or the disease was multiglandular, a total thyroidectomy with a more extensive neck exploration was performed rather than MIP. The success of the operation was determined by measuring the intraoperative intact parathyroid hormone levels in which the reduction of the PTH <50% was accepted as an adequate removal. All of the patients were discharged within 2 days after the operation, and no significant complications were encountered.

Statistical Analysis

All statistical analyses were performed using the Statistical Package for Social Sciences 21 version (IBM Corp.; Armonk, NY, USA). All continuous variables were presented as the mean standard deviation unless otherwise specified. Pre- and post-operative PTH, Ca, and p levels were compared using the paired Student's t-test. The sensitivity, specificity, and diagnostic accuracy of the US and 99 mTc-MIBI scintigraphy were calculated accepting the surgical pathology as a reference method for both per lesions. The true positive (TP) result was defined as correct identification of the parathyroid adenoma side and the level (i.e., if the imaging study identified a lesion in the right-upper quadrant of the disease and the surgery confirmed the presence, then the diag-

nosis was classified as TP). If the pre-operative imaging correctly assessed the side but incorrectly interpreted the level, that case was accepted as the false negative (FN). False-positive results were defined as a pre-operative positive lesion in the relevant location despite negative surgical findings. The following formulas were used to calculate sensitivity, $TP/(TP+FN)$; specificity, $TN/(TN+FP)$; and diagnostic accuracy, $(TP + TN)/(TP+TN+FP+FN)$.

RESULTS

A total of 60 patients, 9 male (15%) and 51 female (85%), with a mean age of 54.78 ± 12.80 years were enrolled in the study. Detailed demographics, and pre- and post-operative biochemical and histological findings of the patients are listed in Table 1. Among 60 patients, 54 had solitary parathyroid adenoma (90%), while five patients (8.3%) had a multiglandular disease, and all of them were hyperplasia. All patients with solitary parathyroid adenoma underwent MIP, except for patients who had a combination of thyroidectomy and parathyroidectomy during the same session. Pre-operative US identified 48/54 (88.9%) of the solitary adenoma, while pre-operative 99 mTc-MIBI planar scintigraphy+SPECT/CT was able to identify all solitary adenomas except for two patients (96.3%). The solitary adenoma missed by the scintigraphy was detected on the pre-operative US. Hence, the combination of pre-operative US and 99 mTc-MIBI planar scintigraphy+SPECT/CT correctly identified all the solitary parathyroid adenomas. Among five patients with multiglandular disease, one had right upper and lower, one had right lower and left upper, two had right lower and left lower, and one had a four-quadrant disease. US was able to identify all multiglandular involvements in four out of five patients (80%) except for the patients with glandular hyperplasia involving all quadrants of the gland. Among these five patients, 4 had parathyroid hyperplasia, and one had two parathyroid adenomas. US was able to correctly identify two out of four of these glandular involvements, yet given to our methodology, this case was accepted as FN. The 99 mTc-MIBI planar scintigraphy+SPECT/CT detected the pathology in three out of five patients (60%) with multiglandular disease. The 99 mTc-MIBI planar scintigraphy+SPECT/CT also could not detect all quadrants in patients with multiglandular disease involving all quadrants and entirely missed the pathology in the other patient. In one patient, both the US and 99 mTc-MIBI planar scintigraphy identified a solitary nodule in the right parathyroid gland, yet surgical exploration could not detect abnormal parathyroid tissue. This patient was scheduled for a follow-up after the operation. Table 2 demonstrates the sensitivity and diagnostic accuracy of the US, 99 mTc-MIBI planar scintigraphy+SPECT/CT, and a combination of these modalities for solitary parathyroid adenoma; Table 3 shows findings of the imaging modalities and the final results of the pathological specimen for multiglandular disease; and Table 4 shows an overall sensitivity and diagnostic accuracy of the US and 99 mTc-MIBI planar scintigraphy+SPECT/CT in detecting parathyroid pathology.

DISCUSSION

In the present study, we demonstrated that while the 99 mTc-MIBI planar scintigraphy+SPECT/CT had a slightly better sensitivity (91.5% vs. 88.1%) and diagnostic accuracy (90% vs. 86.6%) compared to US in identifying parathyroid pathology in patients with PHPT, both of the methods showed sufficient success in accurately determining the location of the pathology. Furthermore, a combination of these methods provided an even better diag-

nostic value (diagnostic accuracy 96.6% and sensitivity 98.3%) for the pre-operative evaluation of the parathyroid lesions.

Ultrasound (US) and 99 mTc-MIBI planar scintigraphy are the standard imaging methods for the pre-operative assessment in the patients with PPTH. In the past century, pre-operative utilization of these modalities was deemed unnecessary for the evaluation of parathyroid adenoma since the primary approach to parathyroid adenoma involved a bilateral conventional surgical exploration of the neck (3, 13). However, the main trend in the surgical approach for parathyroid adenomas has shifted toward minimally invasive procedures substantially depending on the pre-operative imaging studies (4-6). Many studies have explored the diagnostic value and the role of the US, 99 mTc-MIBI planar scintigraphy, and also the 99 mTc-MIBI planar scintigraphy+SPECT/CT in the pre-operative investigations of the patient with PHPT.

The reported sensitivity of US has considerably varied among the studies. In the present study, the overall sensitivity of US was 88.1%, which was favorably comparable to most of the previous reports with a reported sensitivity range 44%-90% (14-21). We suggest that several factors might have led to this wide gap between the studies. First, US is considerably an operator-dependent modality; hence, the experience of the operator seems to be a one of the critical factors resulting in this difference (20, 22). Second, the previous works were conducted within a substantially long timeline; therefore, the technological advancements of the US units might also play an essential role in this issue (14-21).

Furthermore, the location of the parathyroid adenomas might also lead to this difference. It has been well-known that ectopic locations such as the upper mediastinum and the retroesophageal area, or deep location of the adenoma, pose particular challenges for the sonographic evaluation (23, 24). In our study, only two of the 59 patients with surgically proven parathyroid pathology had adenomas located in the upper mediastinum, and US failed to detect both of these lesions, in line with the several previous works (4, 23, 24).

Besides from the evaluation of the parathyroid lesions, US also had several advantages over the 99 mTc-MIBI planar scintigraphy+SPECT/CT. First, US has a better spatial resolution, which allowed the operator to investigate potential thyroid pathology simultaneously, and this advantage might be quite helpful in endemic areas for thyroid disease (25). For instance, 31.7% of the patients in our study cohort underwent total or unilateral thyroidectomy in combination with parathyroid surgery for their additional thyroid pathology. As in conjunction with the several previous works, US showed a better diagnostic performance in multiglandular disease compared to scintigraphy, and correctly detected all the pathological quadrants in four out of five of the patients (80%) (25-27). US is also a cost-effective, portable, non-radiation-bearing modality with widespread availability compared to scintigraphy. Moreover, US also could increase the confidence of the surgeons by confirming scintigraphic findings and, hence, aid surgeons tailoring the best surgical strategy for MIP.

Despite US advantages, the 99 mTc-MIBI planar scintigraphy is commonly accepted as the gold standard modality for the pre-operative evaluation of patients with PHPT (12). The reported sensitivity and diagnostic accuracy of the 99 mTc-MIBI planar scintigraphy was substantially higher compared to US in the pre-

99mTc MIBI+ SPECT/CT combination with US	98.3%	96.6%

*US=ultrasound, 99mTc MIBI+ SPECT/CT=Technetium-99m sestamibi in combination single photon-emission computed tomography/computed tomography

vious works (25-28). The 99 mTc-MIBI planar scintigraphy is also superior to US in detecting ectopic lesions, and in our study, the 99 mTc-MIBI planar scintigraphy+SPECT/CT was able to show two ectopic parathyroid adenomas, where US failed to do so. One of the main disadvantages of the 99 mTc-MIBI planar scintigraphy is its lower spatial and anatomical resolution compared to US, which is currently substantially alleviated by the addition of SPECT/CT to the planar imaging (30). In our study, we did not compare planar imaging with the cross-sectional method, yet the reported diagnostic accuracy of SPECT/CT was higher in previous works (30). In the present work, the main flaw of the 99 mTc-MIBI planar scintigraphy+SPECT/CT was exposed by multiglandular disease in conjunction with the previous reports (25-27). Several authors advocated that dominant increased function of one of the pathological glands in multiglandular disease might reduce the reached tracer to the others, which substantially limits the detection of the glands. Increased expression of a multidrug resistance protein, glycoprotein P, is also considered to limit the MIBI uptake in these patients. P-glycoprotein is coded by the multidrug resistance gene located at the 7th chromosome and results in increased wash-out of the MIBI (30, 31).

There were several limitations to our study. First, the study was retrospectively designed; hence, our findings should be evaluated with precaution. Second, we did not compare SPECT/CT with the planar imaging, as mentioned in the previous paragraphs. Third, we had only two patients with ectopic parathyroid adenoma and five patients with multiglandular disease, which substantially limited us to draw a definite conclusion concerning the diagnostic value of the US and 99 mTc-MIBI planar scintigraphy+SPECT/CT in these patients. Finally, we did not investigate the ability of imaging methods to detect pathology compared to adenomas weight.

CONCLUSION

Ultrasound (US), in the hands of a skilled and experienced operator, and the 99 mTc-MIBI planar scintigraphy+SPECT/CT had separately an excellent diagnostic ability in assessing patients with PHPT in the pre-operative period; however, the combination of these methods showed an even superior diagnostic accuracy and sensitivity reaching up to 96.6% and 98.3, respectively. We highlight that although both of these methods could be separately used as a pre-operative guide for the MIP, their combination should always be preferred.
